RESPONSE OF BLACKBERRY CULTIVARS TO NEMATODE TRANSMISSION OF TOBACCO RINGSPOOT VIRUS

By Alisha Sanny
Department of Horticulture

Faculty Mentors: Professors John R. Clark and Rose Gergerich
Departments of Horticulture and Plant Pathology, respectively

Abstract:

A study was conducted on eight cultivars of blackberry (‘Apache’, ‘Arapaho’, ‘Chester’, ‘Chickasaw’, ‘Kiowa’, ‘Navaho’, ‘Shawnee’, and ‘Triple Crown’), of which four plants of each were previously determined in the fall of 2001 to have root, but not leaf, infection with Tobacco ringspot virus (TRSV). The objective of our study was to determine virus effects on plant vigor, and the spread of virus infection in the plants. Eight plants of each cultivar, four infected and four free of infection, were grown in pots on a gravel pad for the 2002 growing season, and samples of primocane and florican leaves were taken to determine if TRSV had moved to the above-ground portion of the plants. TRSV infection was determined by ELISA tests. At the end of the growing season (October), the plants were harvested and dry weights determined for floricanes, primocanes, and roots to determine virus effects on plant vigor. In all plants that had been shown to have root TRSV infection, the virus was shown to have moved into the top portion of the plants as evidenced by positive ELISA tests on primocane and florican leaf tissue. Dry weight results indicated no significant interaction of virus infection and cultivar, or any main effects of virus on cane or root growth, as all dry weights were similar for infected and non-infected plants. No dramatic leaf symptoms of virus infection were observed on infected plants in our study at any time during the growing season. Further research should focus on possible virus effects on plants that have been infected for a longer period of time to determine if in fact the virus has any effect on plant growth or productivity.

Introduction:

There have been 26 virus or virus-like diseases reported for Rubus crops (blackberries and raspberries) in the world (Jones, 1986). Viruses cause more damage in the black and purple raspberries and less damage in red raspberries and blackberries (Crandall, 1995). Many viruses that infect blackberry do not produce distinctive symptoms, and reports of virus effects on blackberries are very limited. A recent study on the impact of Raspberry bushy dwarf virus (RBDV) on ‘Marion’ blackberry in Oregon showed that there was no virus effect on cane number or length in a two-year period, but that there was a significant yield reduction (50%) in RBDV infected plants, along with reduced berry weight (40%) and drupelet number per berry (39%) (Strik and Martin, 2002). Infected plants also showed visual symptoms, including chlorosis, vein clearing, silver discoloration, and malformed, small fruit. Newly infected plants did not display such distinct symptoms.

There are approximately 200-400 acres of blackberries grown and marketed locally throughout Arkansas. Eleven licensed Arkansas nurseries and 29 licensed nurseries in other states and countries propagate University of Arkansas patented cultivars, as well as other cultivars, for national and international markets (Troxell, 2001). The presence of virus symptoms in nurseries and commercial blackberry fields in Arkansas has been a recent cause for concern. A field survey was conducted in Arkansas of blackberry nurseries for TRSV, RBDV, and Impatiens necrotic spot virus (INSV) in 2002. All three viruses were found, but TRSV was found first and was most prevalent (Rose Gergerich, unpublished).

Leaves of blackberry and dewberry plants in North Carolina infected with TRSV showed faint to severe ringspots, mottling, mosaic, stunting, leaf distortion, and yellow line patterns (Rush and Gooding, 1970). However, they usually did not have symptoms on each cane. Virus symptoms on blackberry plants from Arkansas showed chlorosis, oak-leaf patterns, and mosaic (Troxell, 2001; Fig. 1).

Guzman, et al. (2002) more recently conducted a virus survey in North Carolina, South Carolina, and Virginia in 2001-2002. In North Carolina, TRSV was found in 57% (257/451) of the symptomatic plants tested. TRSV was identified in 33% (21/62) of the samples from South Carolina, but TRSV was not identified in any of the plantings tested in Virginia. TRSV was detected in ‘Apache’ and ‘Arapaho’ most frequently (>50%). It was also detected in ‘Chester’, ‘Chickasaw’, ‘Lochness’, and ‘Rosborough’.

TRSV is a nepovirus that was first reported in Nicotiana tabacum by Fromme et al. (1927). The first report of TRSV in blackberry was published in 1965 from North Carolina (Stace-Smith, 1987). Rush and Gooding (1970) isolated TRSV from
Rubus allegheniensis, R. argutus, R. flagellaris, and an unidentified Rubus species in North Carolina. TRSV has a large host range, including both herbaceous and woody plants (Stace-Smith and Hansen, 1974). It occurs throughout North America, especially in the southeastern United States (Rush and Gooding, 1970).

TRSV virions are isometric, not enveloped, and 25-29 nm in diameter. The genome consists of two single strands of linear RNA, both of which are needed for infection (Brunt et al., 1996). The primary spread of TRSV in the field is by the dagger nematode, Xiphinema americanum. The virus does not multiply in the vector and is lost once the nematode molts. It can also be transmitted mechanically, by infected nursery stock, and by pollen (Brunt et al., 1996).

In the most extensive study of TRSV on blackberry, Troxell (2001) conducted nematode transmission experiments on eight blackberry cultivars (Apache, Arapaho, Chester, Chickasaw, Kiowa, Navaho, Shawnee, and Triple Crown). She infected tissue-cultured plants with TRSV using X. americanum transmission, and found all cultivars were susceptible to this virus as determined by sampling roots of exposed plants and testing for TRSV using Protein-A ELISA tests. ELISA tests revealed that TRSV was not present in the leaves of aboveground portions of these plants during the first growing season following nematode transmission of the virus. Symptoms were seen on primocane leaves of infected plants, but these were mild and transient.

Our study was initiated to further evaluate the virus effects on virus-infected or non-infected plants used in 2001 by Troxell (2001). Specifically, we wanted to determine the impact, if any, of TRSV infection in the second year following nematode transmission on blackberry plant vigor and to find if the virus could be found in aboveground plant portions based on ELISA tests.

Material and Methods: In May 2002, four non-infected and four infected plants of each cultivar used in an earlier study (Troxell, 2001) were chosen for this study. The plants had been grown in 3-L plastic pots the previous season, and had been mulched with sawdust mulch over the winter to protect them from winter injury. In March 2002, the plants were removed from the mulch and pruned, leaving two 0.8-m primocanes. Floricanes were pruned, leaving two "ach. Roots were washed, dried in the same manner, and weighed. The fourth replication was kept for further observation. Dry weight data were analyzed as a two-factor randomized complete block by JMP (JMP, version 4.0. SAS Institute, Inc. Cary, N.C., 1989-2000).

Results and Discussion: All plants of all cultivars that had tested positive in ELISA tests in root samples taken in 2001 tested positive for TRSV in primocane and floricanes in July 2002. The ELISA tests also demonstrated that the non-infected control plants continued to be virus free. The finding that virus was present in the leaves indicates that the virus moved from the roots to the aboveground portion of the plants in the second year after nematode transmission. No virus symptoms were observed on the leaves during the study on infected or non-infected plants.

For the dry weight data, the data analysis of variance indicated no significant interaction of infection status and cultivar for the variables measured. Additionally, the main effect of virus infection status was not different for any variables.
indicates no virus effect on plant vigor. The dry weight means were similar for floricanes, primocanes, and roots (Table 1). Although no significant differences were found between infected and non-infected blackberry plants in this study it is possible that the primocanes which are now virus infected will show symptoms of virus infection when they develop as floricanes next year. Cultivars averaged over plant infection status were significantly different for dry weight of primocanes, floricanes, and roots (data not shown). This finding was not important for this investigation since our effort was to identify virus effects, not cultivar vigor differences.

The most noteworthy finding of our study was the second-year presence of TRSV in leaf samples. This has a number of implications for management of blackberry virus diseases. First, it is important for nursery growers and regulatory agencies because plants that become infected in the field by nematode transmission may be carrying virus in their roots (the portion of the plant often used for propagation) but test negative for virus in their leaves in ELISA tests and appear healthy based on the lack of leaf symptoms. Second, the dynamics of TRSV movement in the plant are clearer from our results. The delay in virus movement from the roots to the aboveground portion of the plant was longer than expected. This area needs further study to determine whether blackberry plants are infected with TRSV second year presence of TRSV during the last year.

Field-grown, mature blackberry plants that express virus symptoms often grow well and bear abundant, good quality fruit. This has raised the question "What is the effect of viruses such as TRSV on blackberries". Our data on second-year plants indicates no virus effect on total plant growth. However, the virus may have greater effects the third year as it spreads further in the plant. Also, our plants did not bear fruit, thus we were unable to determine if TRSV-infected plants produced fruit that was malformed, crumby, or otherwise possibly affected by virus infection. Additionally, if blackberry plants become infected with more than one virus, the combined effects of these viruses often produce severe disease symptoms.

The concerns of blackberry nursery stock producers are somewhat different from those of blackberry fruit producers. Many states and countries have regulatory agencies that restrict the movement of plants that are not certified as virus-tested. Blackberry plants expressing symptoms of virus infection would be denied entrance by such regulatory agencies. Based on the results of the research reported here, the absence of virus symptoms in blackberry leaves should not be used to determine whether blackberry plants are infected with TRSV.

Faculty Comment:

Professor John Clark, one of Ms. Sanny's faculty mentors made the following remarks about her work:

I have served as Ms. Sanny's undergraduate advisor, and co-advisor for her research project. Working with her has been a true joy! She came to the University as a freshman Chancellor's Scholar, and has excelled academically. I cannot overstate the extraordinary academic performance by her while enrolled here. She also has been an exemplary undergraduate researcher. She was able to undertake this study and complete it very well, and prepare the manuscript in a very timely manner.

The research study, co-advised with Dr. Rose Gergerich in Plant Pathology, dealt with investigating the movement or within-plant spread of Tobacco ringspot virus in a number of blackberry cultivars. This virus is of prime importance in Arkansas and other southern states as it is being found in commercial blackberry fields commonly. However, little is known of its movement in the plant or the overall effect of the virus on the plant. Her study showed that after infection, the virus moved into the above-ground parts of the plants the following year. She also found that from an overall plant vigor standpoint that the virus did not affect the plant's growth in the second year after infection. These are both findings that have not been reported in blackberry before. This information will be useful for further research on this topic, and also will contribute to better inspection by Arkansas State Plant Board of blackberry nurseries that propagate these cultivars.
